# 1. Sorting Algorithms

Sorting is the process of arranging elements in a specific order (typically ascending or descending). This section covers eight fundamental sorting algorithms, their properties, complexity analysis, and recurrence relations.

**Key Terminology:**

- **Stable:** Equal elements keep their original relative order
- **In-place:** Uses $O(1)$ extra space (no large auxiliary arrays)
- **Adaptive:** Faster when input is partially sorted
- **Comparison-based:** Sorts by comparing elements (lower bound: $\Omega(n \log n)$)

## 1.1 Complete Comparison Table

| Name | Type | Stable | In-place | Best | Average | Worst | Space | Adaptive | Recurrence |
|---|---|---|---|---|---|---|---|---|---|
| **Insertion** | Incremental | Yes | Yes | $O(n)$ | $O(n^2)$ | $O(n^2)$ | $O(1)$ | Yes | $T(n) = T(n-1) + O(n)$ |
| **Selection** | Incremental | No | Yes | $O(n^2)$ | $O(n^2)$ | $O(n^2)$ | $O(1)$ | No | $T(n) = T(n-1) + O(n)$ |
| **Bubble** | Incremental | Yes | Yes | $O(n)$ | $O(n^2)$ | $O(n^2)$ | $O(1)$ | Yes | $T(n) = T(n-1) + O(n)$ |
| **Merge** | Divide & Conquer | Yes | No | $O(n \log n)$ | $O(n \log n)$ | $O(n \log n)$ | $O(n)$ | No | $T(n) = 2T(n/2) + O(n)$ |
| **Quick** | Divide & Conquer | No | Yes | $O(n \log n)$ | $O(n \log n)$ | $O(n^2)$ | $O(\log n)$ avg | No | $T(n) = 2T(n/2) + O(n)$ avg |
| **Heap** | Tree-based | No | Yes | $O(n \log n)$ | $O(n \log n)$ | $O(n \log n)$ | $O(1)$ | No | $T(n) = T(n-1) + O(\log n)$ |

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| **Counting** | Count-based | Yes | No | $O(n+k)$ | $O(n+k)$ | $O(n+k)$ | $O(k)$ | No | $T(n) = T(n-1) + O(1)$ |
| **Radix** | Count-based | Yes | No | $O(d(n+k))$ | $O(d(n+k))$ | $O(d(n+k))$ | $O(n+k)$ | No | $T(n) = T(n-1) + O(d)$ |

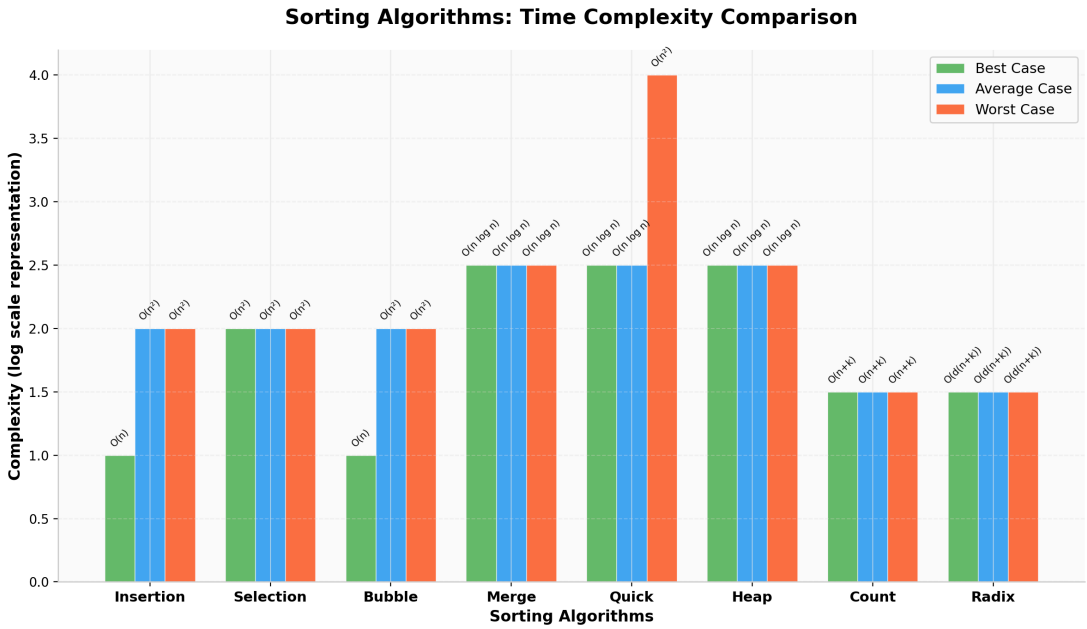

**Figure 1:** *Time complexity comparison across all sorting algorithms (Best, Average, and Worst cases)*

## 1.2 Individual Algorithm Explanations

### Insertion Sort

Builds the sorted array one element at a time by taking each element and inserting it into its correct position in the already-sorted portion. Like sorting playing cards in your hand.

### Selection Sort

Repeatedly finds the minimum element from the unsorted portion and places it at the beginning. Makes $O(n)$ swaps total, but always $O(n^2)$ comparisons.

### Bubble Sort

Repeatedly steps through the list, compares adjacent elements and swaps them if they are in the wrong order. Each pass "bubbles" the largest unsorted element to its correct position.

### Merge Sort

Divide-and-conquer: divides the array into halves, recursively sorts each half, then merges the sorted halves. Guaranteed $O(n \log n)$ performance but requires $O(n)$ auxiliary space.

### Quick Sort

Picks a pivot element, partitions the array around the pivot (elements smaller go left, larger go right), then recursively sorts the subarrays. Fastest in practice but $O(n^2)$ worst case.

### Heap Sort

Builds a max-heap from the input, then repeatedly extracts the maximum element and places it at the end. In-place $O(n \log n)$ sort using the heap data structure.

### Counting Sort

Non-comparison sort that counts occurrences of each distinct element, then computes prefix sums to determine positions. Effective when range $k$ is small relative to $n$.

### Radix Sort

Sorts digit by digit, starting from least significant digit (LSD) to most significant (MSD), using a stable sort (typically Counting Sort) as the subroutine.

## 1.3 Average Case Analysis

| Algorithm | Average Case | Why It Matters | Key Insight |
|---|---|---|---|
| Insertion Sort | $O(n^2)$ | $O(n)$ for nearly sorted data | Shifts elements; fewer shifts when almost sorted |
| Quick Sort | $O(n \log n)$ | Good pivot splits array roughly in half | Random/median pivot gives balanced partitions |
| Merge Sort | $O(n \log n)$ | Predictable; always consistent | Preferred when stability is required |
| Heap Sort | $O(n \log n)$ | No worst-case advantage | Heapify takes $\log n$ per element; no adaptivity |

## 1.4 Viva Questions & Answers

## Viva Q&A: Sorting Algorithms

### Q1: Which sorting algorithms are adaptive and why does this matter?

Only Insertion Sort and Bubble Sort are adaptive. They detect sorted portions and stop early, achieving $O(n)$ best-case time. This matters for nearly-sorted data where they outperform even $O(n \log n)$ algorithms.

### Q2: Why does Quick Sort have $O(n^2)$ worst case and when does it occur?

When the pivot is consistently the smallest or largest element (e.g., already sorted array with first/last element as pivot), partitioning creates one subarray of size $n - 1$ and one of size 0, leading to $T(n) = T(n-1) + O(n) = O(n^2)$.

### Q3: Why are Counting Sort and Radix Sort not comparison-based?

They examine the structure of keys directly (digit values, frequencies) rather than comparing elements pairwise. Therefore, the $\Omega(n \log n)$ lower bound for comparison sorts does not apply to them.

### Q4: Is Merge Sort always better than Quick Sort?

No. Merge Sort guarantees $O(n \log n)$ but needs $O(n)$ extra space. Quick Sort is faster in practice (better cache performance, in-place) but has $O(n^2)$ worst case. The choice depends on whether stability and guaranteed bounds are needed.

### Q5: Solve $T(n) = 2T(n/2) + O(n)$ using the Master Theorem.

Here $a = 2, b = 2, f(n) = O(n)$. Since $\log_2 2 = 1$ and $f(n) = \Theta(n^{\log_b a})$, we are in Case 2. Therefore, $T(n) = \Theta(n \log n)$. This applies to Merge Sort and average-case Quick Sort.

### Q6: Why is Heap Sort not stable?

During the heapify process and extraction of max elements, elements with equal values may change their relative order because the heap structure does not preserve input ordering for equal keys.

# 2. Searching Algorithms

Searching algorithms find the position of a target element within a data structure. This section covers the two fundamental searching approaches: Linear Search and Binary Search.

## 2.1 Linear and Binary Search Comparison

| Property | Linear Search | Binary Search |
|---|---|---|
| **Approach** | Sequential scan | Divide & Conquer |
| **Array Requirement** | Unsorted | Sorted |
| **Best Case** | $O(1)$ — element at first position | $O(1)$ — element at middle |
| **Average Case** | $O(n)$ | $O(\log n)$ |
| **Worst Case** | $O(n)$ — element at end or absent | $O(\log n)$ — element at ends or absent |
| **Space** | $O(1)$ iterative | $O(1)$ iterative, $O(\log n)$ recursive |
| **Recurrence** | $T(n) = T(n-1) + O(1)$ | $T(n) = T(n/2) + O(1)$ |
| **Key Feature** | Checks every element one-by-one | Eliminates half the array each step |
| **Data Structure** | Array or Linked List | Only Array (needs random access) |

## 2.2 Detailed Analysis

### Linear Search

Scans the array sequentially from the first element until the target is found or the end is reached. Requires no preprocessing and works on any data structure with sequential access.

### Binary Search

Requires a sorted array. Repeatedly compares the target with the middle element: if the target is smaller, search the left half; if larger, search the right half. Each step halves the search space.

> **Critical Insight:** Binary Search needs $O(1)$ random access to the middle element. Linked Lists have $O(n)$ access time to reach the middle, defeating the purpose of halving the search space.

## 2.3 Viva Questions & Answers

### Viva Q&A: Searching Algorithms

**Q1: Why can't Binary Search work on Linked Lists?**

Binary Search requires $O(1)$ random access to the middle element. In a Linked List, reaching the middle takes $O(n)$ time, which nullifies the $O(\log n)$ advantage. Each "halving" step would cost $O(n)$, resulting in $O(n)$ total time — no better than Linear Search.

**Q2: When is Linear Search better than Binary Search?**

For small arrays or unsorted data. The overhead of sorting ($O(n \log n)$) plus binary searching may exceed a simple linear scan. For $n < 20$, Linear Search is often faster due to better cache locality and fewer branch mispredictions.

**Q3: Solve $T(n) = T(n/2) + 1$ using the Master Theorem.**

Here $a = 1, b = 2, f(n) = 1 = O(n^0)$. Since $\log_2 1 = 0$ and $f(n) = \Theta(n^0)$, we are in Case 2. Therefore, $T(n) = \Theta(\log n)$.

**Q4: How many comparisons in worst-case unsuccessful Binary Search?**

$\lceil \log_2(n+1) \rceil$ comparisons, which is approximately $\log_2 n$. This occurs when the search space is reduced to empty after repeatedly halving.

**Q5: What is the minimum number of comparisons needed to find an element among $n$ elements using comparison-based search?**

$\Omega(\log n)$ in the worst case, by the same decision tree argument as sorting. There are $n+1$ possible outcomes ($n$ positions + not found), so the decision tree needs height at least $\log(n+1)$.

# 3. Graph Algorithms

Graph algorithms process graphs (collections of vertices $V$ and edges $E$) to solve problems like traversal, shortest paths, minimum spanning trees, and cycle detection.

## 3.1 Complete Comparison Table

| Name | Type | Purpose | Data Structure | Best | Average | Worst | Space |
|---|---|---|---|---|---|---|---|
| **BFS** | Traversal | Level-order traversal, shortest path in unweighted graphs | Queue + Adj. List | $O(V+E)$ | $O(V+E)$ | $O(V+E)$ | $O(V)$ |
| **DFS** | Traversal | Path finding, cycle detection, topological sort | Stack (or recursion) + Adj. List | $O(V+E)$ | $O(V+E)$ | $O(V+E)$ | $O(V)$ |
| **Prim's** | MST | Minimum Spanning Tree (dense graphs) | Min-Heap + Adj. List | $O(E+V\log V)$ | $O(E\log V)$ | $O(E\log V)$ | $O(V)$ |
| **Kruskal's** | MST | Minimum Spanning Tree (sparse graphs) | Disjoint Set (Union-Find) + sorted edges | $O(E\log E)$ | $O(E\log E)$ | $O(E\log E)$ | $O(V)$ |
| **Dijkstra's** | Shortest Path | Single-source shortest path (non-negative weights) | Min-Heap + Adj. List | $O(V\log V+E)$ | $O(E\log V)$ | $O(V^2)$ or $O(E\log V)$ with heap | $O(V)$ |
| **Kahn's** | Topological Sort | Linear ordering of DAG | Queue + In-degree array | $O(V+E)$ | $O(V+E)$ | $O(V+E)$ | $O(V)$ |
| **isDAG?** | Cycle Detection | Check if directed graph is acyclic | DFS or Kahn's | $O(V+E)$ | $O(V+E)$ | $O(V+E)$ | $O(V)$ |

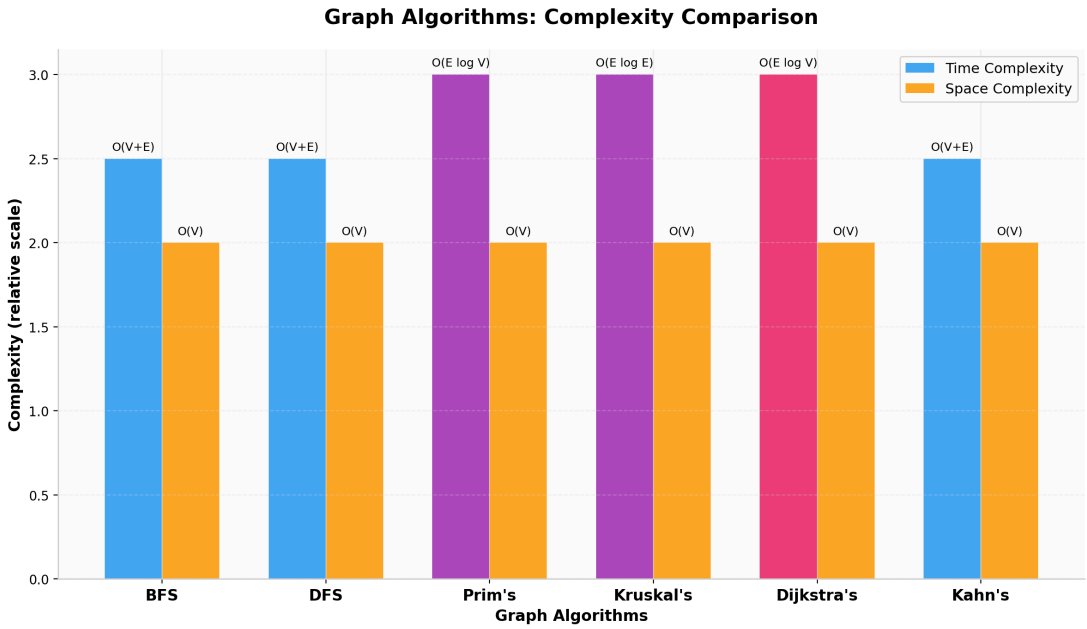

**Figure 3:** *Time and space complexity comparison of graph algorithms*

## 3.2 BFS vs DFS Analysis

| Aspect | BFS | DFS |
|---|---|---|
| **Data Structure** | FIFO Queue | LIFO Stack / Recursion |
| **Exploration** | Level by level (shallow first) | Deep first, then backtrack |
| **Shortest Path** | Yes (unweighted graphs) | No |
| **Cycle Detection** | Yes (undirected) | Yes (directed & undirected) |
| **Applications** | Social networks, GPS, web crawling | Maze solving, topological sort, SCC |

## 3.3 MST: Prim's vs Kruskal's

| Aspect | Prim's Algorithm | Kruskal's Algorithm |
|---|---|---|
| **Approach** | Vertex-based (grow single tree) | Edge-based (add cheapest safe edge) |
| **Best For** | Dense graphs ($E \approx V^2$) | Sparse graphs (few edges) |
| **Cycle Check** | Implicit (always connected) | Union-Find with path compression |

| | |
|---|---|
| **Same Result?** | Yes, both give MST (if edge weights are unique) |

## 3.4 Dijkstra's and Topological Sort

### Dijkstra's Algorithm

Greedy algorithm that always picks the vertex with minimum tentative distance and relaxes its outgoing edges. Fails with negative edge weights because once a vertex is extracted from the heap, its shortest path is finalized, but a negative weight later could offer a shorter path.

> **BFS is Dijkstra with all weights = 1:** When all edge weights are equal (or unweighted), Dijkstra's algorithm degenerates to BFS, as the priority queue becomes a simple FIFO queue.

### Kahn's Algorithm for Topological Sort

Processes nodes with in-degree 0 first, reduces in-degrees of neighbors, and repeats. If all nodes are processed, the graph is a DAG. If nodes remain with in-degree > 0, a cycle exists.

## 3.5 Viva Questions & Answers

### Viva Q&A: Graph Algorithms

**Q1: BFS vs DFS — when to use which?**

Use BFS for: shortest path in unweighted graphs, level-order traversal, finding nodes at a specific distance. Use DFS for: cycle detection, topological sort, exploring all paths, backtracking problems, finding strongly connected components.

**Q2: Why does Dijkstra fail with negative weights?**

Dijkstra's greedy assumption: once a node is extracted from the heap, its shortest path is finalized. Negative edge weights discovered later could offer a shorter path, but Dijkstra never revisits finalized nodes. Use Bellman-Ford for graphs with negative weights.

**Q3: How to detect a cycle in an undirected graph using DFS?**

If an adjacent vertex is already visited AND it is not the parent of the current vertex in the DFS tree, a cycle exists. For directed graphs, a back edge to a vertex in the current recursion stack indicates a cycle.

**Q4: Prim's vs Kruskal's — which is better?**

Prim's: $O(E \log V)$ with binary heap, better for dense graphs ($E \approx V^2$). Kruskal's: $O(E \log E)$, better for sparse graphs (few edges). For dense graphs, Prim's avoids the $O(E \log E)$ sorting overhead.

**Q5: Kahn's algorithm — what if multiple nodes have in-degree 0?**

Any order of processing is valid. The queue processes them, resulting in a topological sort that is not unique. A DAG can have multiple valid topological orderings.

**Q6: Prove that a topological sort exists iff the graph is a DAG.**

If the graph has a cycle, nodes in the cycle always have in-degree at least 1 from within the cycle, so they never enter the queue in Kahn's algorithm. If all nodes are processed (Kahn's succeeds), no cycle existed. Conversely, every DAG has at least one source (in-degree 0), which can be placed first; removing it leaves a smaller DAG, so by induction a topological order exists.

# 4. Theorem 8.1: Comparison Sort Lower Bound

**Theorem 8.1**

Any comparison sort algorithm requires $\Omega(n \log n)$ comparisons in the worst case.

This theorem establishes a fundamental limit on how fast any comparison-based sorting algorithm can possibly be. No algorithm that sorts solely by comparing pairs of elements can do better than $n \log n$ time in the worst case.

## 4.1 The Decision Tree Model

To prove this lower bound, we model any comparison sort as a **decision tree**:

- Each **internal node** represents one comparison between two elements $(a_i \leq a_j?)$
- Each **branch** represents the outcome (Yes/No) of that comparison
- Each **leaf** represents one sorted permutation (one possible output)

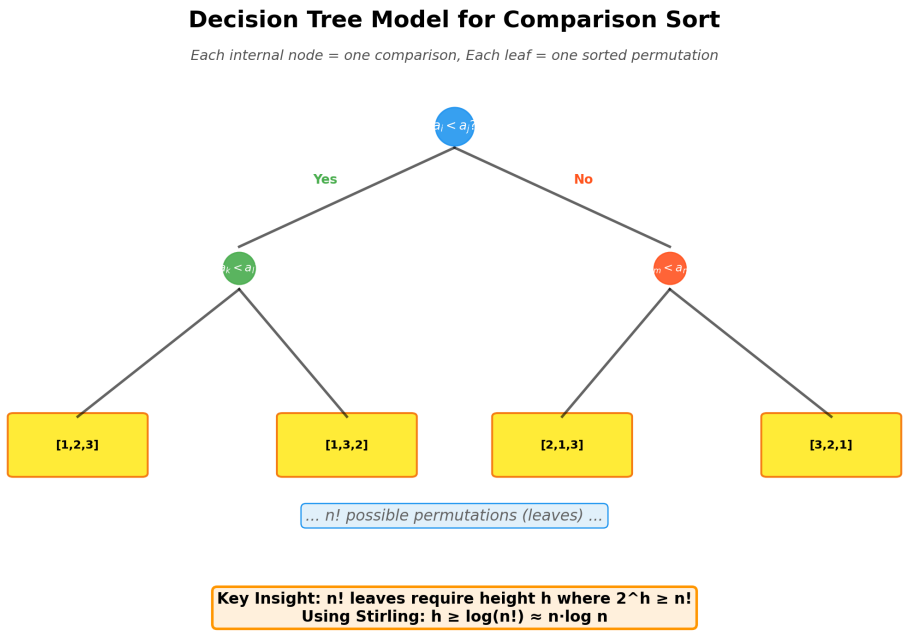

**Figure 4:** *Decision tree model showing comparisons leading to sorted permutations*

For $n$ distinct elements, there are $n!$ possible permutations. Each permutation must appear as a leaf in the decision tree (otherwise that ordering would be unreachable).

$$\text{Number of leaves} \geq n!$$

### Step 2: Apply Binary Tree Height Property

For any binary tree of height $h$: $\text{leaves} \leq 2^h$.

Combining with Step 1:

$$n! \leq \text{leaves} \leq 2^h$$

### Step 3: Solve for $h$

Taking logarithms:

$$h \geq \log(n!)$$

Using **Stirling's approximation**: $\log(n!) \approx n \log n - n \log e + O(\log n)$

Therefore:

$$h \geq \log(n!) = \Omega(n \log n)$$

The height $h$ of the decision tree equals the worst-case number of comparisons. Therefore, any comparison sort requires $\Omega(n \log n)$ comparisons in the worst case.

**What This Proves vs. What It Does NOT Prove:**

- **Proves:** Merge Sort and Heap Sort are asymptotically optimal among comparison sorts
- **Does NOT prove:** Non-comparison sorts (Counting, Radix) are impossible or that $O(n)$ sorting is impossible by any method

## 4.3 Viva Questions & Answers

### Viva Q&A: Theorem 8.1

**Q1: State Theorem 8.1 in one line.**

Any comparison sort algorithm requires $\Omega(n \log n)$ comparisons in the worst case.

**Q2: Why does the decision tree need at least $n!$ leaves?**

Because there are $n!$ possible input permutations, and the algorithm must be able to produce the correct sorted order for every one. If any permutation is missing as a leaf, that input ordering cannot be correctly sorted.

**Q3: Is Merge Sort optimal? Prove.**

Yes. Merge Sort achieves $\Theta(n \log n)$ worst-case time, which matches the $\Omega(n \log n)$ lower bound. Therefore it is asymptotically optimal — no comparison sort can be more than a constant factor faster.

**Q4: Why is Quick Sort's worst case $O(n^2)$ not a contradiction to Theorem 8.1?**

The theorem states $\Omega(n \log n)$ — this is a lower bound (minimum). Quick Sort's average case is $\Theta(n \log n)$, which satisfies the bound. The $O(n^2)$ worst case exceeds the bound, which is allowed — the bound says you cannot do better, not that you must achieve exactly it.

**Q5: Can we sort in $O(n)$ time?**

Yes, but not by comparisons. Counting Sort ($O(n + k)$) and Radix Sort ($O(d(n + k))$) achieve linear time by exploiting the structure of keys (integer ranges, digits), bypassing the comparison model entirely. Theorem 8.1 only applies to comparison-based sorts.

**Q6: Explain the role of Stirling's approximation in the proof.**

Stirling's approximation states $\log(n!) \approx n \log n$. This transforms $\log(n!)$ into the familiar $\Omega(n \log n)$ form, giving us the clean lower bound expression used in the theorem statement.

# 5. Corollary 8.2: Asymptotically Optimal Sorts

**Corollary 8.2**

Heap Sort and Merge Sort are asymptotically optimal comparison sorts.

Since any comparison sort requires $\Omega(n \log n)$ comparisons (Theorem 8.1), and both Heap Sort and Merge Sort achieve $O(n \log n)$ worst-case time complexity, they match the theoretical lower bound. Therefore, they are as efficient as any comparison sort can ever be (up to constant factors).

### Why Only These Two?

| Algorithm | Worst Case | Matches $\Omega(n \log n)$? | Asymptotically Optimal? |
|---|---|---|---|
| Merge Sort | $O(n \log n)$ | Yes | **Yes** |
| Heap Sort | $O(n \log n)$ | Yes | **Yes** |
| Quick Sort | $O(n^2)$ | No | No (worst case) |
| Insertion Sort | $O(n^2)$ | No | No |
| Selection Sort | $O(n^2)$ | No | No |
| Bubble Sort | $O(n^2)$ | No | No |

**Examiner Trap:** "Is Quick Sort asymptotically optimal?" **Answer:** "No, because its worst case is $O(n^2)$, which exceeds the $\Omega(n \log n)$ lower bound. It is optimal only in the average case."

## 5.1 Viva Questions & Answers

### Viva Q&A: Corollary 8.2

**Q1: What does "asymptotically optimal" mean?**

For large $n$, ignoring constant factors, the algorithm cannot be improved upon within the same computational model. Its worst-case performance matches the theoretical lower bound.

**Q2: Why is Quick Sort NOT included in Corollary 8.2?**

Quick Sort's worst case is $O(n^2)$, which exceeds the $\Omega(n \log n)$ lower bound. The corollary specifically refers to worst-case optimality. Quick Sort is optimal only in the average case.

**Q3: Why do Merge Sort and Heap Sort achieve the bound?**

Merge Sort uses divide-and-conquer: $T(n) = 2T(n/2) + O(n) \to \Theta(n \log n)$ by Master Theorem. Heap Sort builds a heap in $O(n)$ and performs $n$ extract-max operations at $O(\log n)$ each, giving $O(n \log n)$ total.

**Q4: Does asymptotic optimality mean these are the best sorting algorithms to use always?**

No. "Asymptotically optimal" only concerns growth rate. Quick Sort is often faster in practice due to better cache performance. Non-comparison sorts can achieve $O(n)$ for specific data types. The choice depends on the specific requirements.

# 6. Lemmas 8.3 & 8.4: Radix Sort Analysis

**Lemma 8.3: Radix Sort with d Digits**

Given $n$ numbers, each with $d$ digits, where each digit takes $k$ possible values $(0 \text{ to } k-1)$, Radix Sort correctly sorts them in $\Theta(d(n+k))$ time, using a stable sort that takes $\Theta(n+k)$ time.

## The Idea

Radix Sort processes digits from least significant to most significant (LSD to MSD). After sorting on the $i$-th digit, the numbers are sorted by their lowest $i$ digits. Stability is crucial: it preserves the ordering from previous (less significant) digit sorts.

## Time Analysis

| Component | Cost | Reason |
|---|---|---|
| One digit sort | $\Theta(n+k)$ | Counting Sort on $n$ items with range $k$ |
| $d$ digits total | $\Theta(d(n+k))$ | Repeat $d$ times |

**Lemma 8.4: Radix Sort with b-bit Numbers**

Given $n$ numbers, each $b$ bits long. Choose any $r \leq b$ (bits per "digit"). Radix Sort sorts them in $\Theta\left(\frac{b}{r}(n+2^r)\right)$ time, using stable sort with range $0$ to $k = 2^r - 1$.

## Parameter Selection

| Parameter | Meaning |
|---|---|
| $b$ | Total bits per number |
| $r$ | Bits per "digit" (we treat $r$ bits as one digit) |
| $b/r$ | Number of digit positions (rounds of sorting) |
| $2^r$ | Range of each digit ($k = 2^r$ possible values) |

## Optimization: Choosing $r$

To minimize $\frac{b}{r}(n + 2^r)$, balance the terms by setting $n \approx 2^r$, which gives $r = \log_2 n$:

$$\text{Time} = \Theta\left(\frac{b}{\log n}(n + n)\right) = \Theta\left(\frac{bn}{\log n}\right)$$

For $b = O(\log n)$ (numbers fit in a machine word): Time $= \Theta(n)$ — **linear time sorting!**

## 6.1 Viva Questions & Answers

### Viva Q&A: Lemmas 8.3 & 8.4

**Q1: Why must the intermediate sort in Radix Sort be stable?**

Stability ensures that when two numbers have the same digit in the current position, their relative order from previous (less significant) digit sorts is preserved. Without stability, earlier sorting work is destroyed, and the final result may not be correctly sorted.

**Q2: Prove Lemma 8.3 by induction.**

**Base case:**$d = 1$. One counting sort correctly sorts by a single digit. **Inductive step:** Assume correct for $d - 1$ digits. For $d$ digits: stable sort on digit $d$ preserves order of numbers with equal digit $d$ (by stability), and those were already sorted on lower $d - 1$ digits by the inductive hypothesis.

**Q3: What is the best choice of $r$ in Lemma 8.4?**

$r = \log_2 n$ balances $n$ and $2^r$, making $n + 2^r = \Theta(n)$. With $b/\log n$ rounds, the total time becomes $\Theta(bn/\log n)$. For $b = O(\log n)$, this yields $\Theta(n)$ linear time.

**Q4: Why isn't Radix Sort $\Omega(n \log n)$ like comparison sorts?**

Radix Sort is not comparison-based! It inspects bits/digits directly rather than comparing elements pairwise. Theorem 8.1's lower bound applies only to comparison sorts, so non-comparison sorts like Radix can achieve $O(n)$ time.

**Q5: When is Radix Sort preferred over Quick Sort or Merge Sort?**

When keys are integers with bounded range (e.g., 32-bit integers), and $d$ and $k$ are constants or small relative to $n$. Radix Sort gives guaranteed $O(n)$ time in these cases, while comparison sorts are always $\Omega(n \log n)$.

**Q6: What happens if $r = b$ in Lemma 8.4?**

If $r = b$, then $b/r = 1$ (one round), and $k = 2^b$. This reduces to a single Counting Sort with range $2^b$, taking $\Theta(n + 2^b)$ time. This is practical only when $2^b$ is not too large.

# 7. Algorithm Improvements

This section summarizes practical improvements for all eight sorting algorithms, including the reasoning and complexity impact.

## 7.1 Summary Table of All Improvements

| Algorithm | Improvement | Time Before | Time After | Space | Key Benefit |
|---|---|---|---|---|---|
| **Insertion** | Binary search for position | $O(n^2)$ comparisons | $O(n \log n)$ comparisons | $O(1)$ | Fewer comparisons |
| | Shell Sort (gap sequence) | $O(n^2)$ | $O(n \log^2 n)$ | $O(1)$ | Much faster on medium arrays |
| **Selection** | Heap-based selection (Heap Sort) | $O(n^2)$ | $O(n \log n)$ | $O(1)$ | Optimal comparison sort |
| | Bidirectional (Cocktail) | $O(n^2)$ | $O(n^2)$ (2x faster) | $O(1)$ | Better constant factor |
| **Bubble** | Early exit flag | $O(n^2)$ best | $O(n)$ best (adaptive) | $O(1)$ | Adaptive to nearly sorted |
| | Cocktail/Shaker Sort | $O(n^2)$ | $O(n^2)$ (2x faster) | $O(1)$ | Better constant factor |
| **Merge** | Hybrid with Insertion (Timsort) | $O(n \log n)$ | $O(n \log n)$ | $O(n)$ | 20-30% faster in practice |
| | Bottom-up (iterative) | $O(n \log n)$ | $O(n \log n)$ | $O(n)$ | No recursion overhead |
| | Multiway ($k$-way) | $O(n \log n)$ | $O(n \log_k n)$ | $O(n)$ | External sorting |
| **Quick** | Randomized pivot | $O(n^2)$ worst | $O(n \log n)$ expected | $O(\log n)$ | Eliminates adversarial input |
| | Median-of-three pivot | $O(n^2)$ worst | $O(n^2)$ rare | $O(\log n)$ | Simple, no RNG needed |
| | Introsort (Quick + Heap) | $O(n^2)$ worst | $O(n \log n)$ guaranteed | $O(\log n)$ | Best of both worlds |
| | 3-way partitioning | $O(n^2)$ on dups | $O(n)$ on all-equal | $O(\log n)$ | Handles duplicates |
| **Heap** | Floyd's $O(n)$ build | $O(n \log n)$ build | $O(n)$ build | $O(1)$ | 2x faster construction |
| | Smoothsort / Ternary | $O(n \log n)$ | $O(n)$ best case | $O(1)$ | Adaptive to sorted data |

| | | | | | |
|---|---|---|---|---|---|
| **Counting** | In-place variant | $O(n+k)$ time | $O(n+k)$ time | $O(k) \to O(1)$ | Memory efficient |
| | Cache-blocking | $O(n+k)$ time | $O(n+k)$ time | $O(k)$ | Better cache performance |
| **Radix** | MSD first with recursion | $O(d(n+k))$ | $O(d(n+k))$ | $O(n+k)$ | Faster on well-distributed data |
| | In-place (American Flag) | $O(d(n+k))$ | $O(d(n+k))$ | $O(n+k) \to O(1)$ | Memory efficient |
| | Cache-conscious (tiling) | $O(d(n+k))$ | $O(d(n+k))$ | $O(n+k)$ | 2-5x faster in practice |

## 7.2 Key Takeaways

### Hybrid Approaches

Combine algorithms to exploit strengths: Quick + Heap (Introsort), Merge + Insertion (Timsort)

### Reduce Constants

Cache optimization, recursion elimination, better pivot selection all improve practical performance

### Guarantee Worst-Case

Randomization and Introsort provide $O(n \log n)$ certainty without sacrificing average-case speed

### Adaptivity

Detect nearly-sorted data to achieve $O(n)$ performance when possible

### Space vs Time Tradeoffs

In-place variants trade implementation complexity for memory savings

## 7.3 Viva Questions & Answers

### Viva Q&A: Algorithm Improvements

**Q1: What is the main idea behind Shell Sort?**

Shell Sort improves Insertion Sort by sorting elements far apart first (using a gap sequence), then progressively reducing the gap. This creates "roughly sorted" arrays early, making the final passes with small gaps much more efficient. Time complexity depends on the gap sequence: $O(n \log^2 n)$ or better.

**Q2: How does Introsort guarantee $O(n \log n)$ worst case?**

Introsort begins with Quick Sort but tracks recursion depth. If depth exceeds $2\lfloor \log_2 n \rfloor$, it switches to Heap Sort for that subarray. This combines Quick Sort's average-case speed with Heap Sort's worst-case guarantee.

### Q3: Why does 3-way partitioning help with duplicate elements?

Standard Quick Sort partitions into $\leq$ and $>$ pivot. With many duplicates, all equal elements go to one side, creating unbalanced partitions ($O(n^2)$). 3-way partitioning creates three regions: $<$ pivot, $=$ pivot, $>$ pivot. Elements equal to pivot are already in final position, giving $O(n)$ time for all-equal arrays.

### Q4: Explain Floyd's $O(n)$ heap construction.

Instead of inserting $n$ elements one by one ($O(n \log n)$), Floyd's method starts from the last non-leaf node and heapifies downward. Most nodes are at low levels with small heights. The sum $\sum_{h=0}^{\log n} n/2^{h+1} \cdot O(h) = O(n)$, giving linear build time.

### Q5: What is the practical benefit of Timsort (Merge + Insertion hybrid)?

Timsort switches to Insertion Sort for small subarrays (typically $< 32$ elements), where Insertion Sort has better constant factors and cache performance. For larger arrays, Merge Sort dominates. This hybrid approach is 20-30% faster in practice and is used in Python's `sort()` and Java's `Arrays.sort()`.

### Q6: Why would you choose MSD Radix Sort over LSD?

MSD Radix Sort can terminate early if buckets are small (e.g., bucket size $= 1$), making it adaptive to the data distribution. It's particularly useful for variable-length keys like strings, where some buckets may need no further sorting. LSD always processes all $d$ digits.
